METHOD AND SYSTEM FOR REDUCING FALSE DETECTIONS OF ACCESS SIGNALS

ABSTRACT OF THE DISCLOSURE

A demodulator determines a time of arrival of Access signals that do not result in a access signal. time of arrival are discarded. Upon obtaining a time of arrival, the access signal is equalized and a training sequence of bits in the equalized access signal compared to a reference sequence of bits. A burst is obtained in the confidence metric comparison summing the number of matching bits. The access signal is discarded if the burst confidence metric is less than a threshold number. A decoder performs a parity check on signals that have a burst confidence metric access exceeding the threshold number. The access signal discarded if the parity check fails. Upon passing the the access signal is re-encoded and parity check, compared to its received version. If a number of errors from the comparison exceeds a bit error threshold, the access signal is discarded.
